ABSTRACT

The redox properties of ceria make it suitable as a catalyst or support in oxidation reactions. Ceria-supported transition metal nanoparticles or isolated single atoms provide a metal-support interface that reduces the energy cost to remove interfacial oxygen atoms, providing active oxygen species that can participate in Mars van Krevelen oxidation processes. CO oxidation is a key probe reaction to test the reducibility of ceria-supported catalysts and is also practically important in the elimination of CO at relatively low temperatures in various applications. Preferential oxidation of CO (PROX) in excess H₂ controls the CO concentration to ultra-low levels to prevent poisoning of hydrogen oxidation electrocatalysts. The reactivity of catalysts in CO oxidation and selectivity towards CO over H₂ in PROX is dependent on the type and dispersion of metal species, the structural and chemical properties of CeO₂, and the synthetic preparation methods of the catalysts. In this review, we summarize recently published works on catalytic CO oxidation and PROX reactions on ceria-supported metal nanoparticles and single atoms. We summarize the reactivity on different supported metals, and on different CeO₂ surfaces with the same metal. We summarize the most likely reaction mechanisms as suggested by density functional theory calculations. The factors contributing to selectivity towards CO oxidation in PROX reactions on various supported metals are also discussed.

1. Introduction

CeO₂ is a versatile catalytic material which has generated considerable interest in both academia and industry. Since CeO₂ was first employed by the Ford Motor Company as an oxygen storage component in car converters in 1976, the inclusion of CeO₂ as a key component in three-way catalysts (TWCs) has escalated dramatically in the automobile industry [1]. Beyond commercial applications, ceria-based catalysis has been

extensively studied for numerous reactions, including CO oxidation, preferential oxidation of CO (PROX) over H₂, water-gas shift (WGS), methane combustion, selective hydrogenations, oxidation of light organic compounds, and C–C coupling reactions [2–6].

Ceria is a yellow or white powder that crystallizes in the fluorite structure with a *Fm*3*m* space group and a face-centered cubic (fcc) unit cell. Cerium has a 4*f*²5*s*²5*p*⁶6*s*² electron configuration and exhibits both +3 and +4 oxidation states, leading to

the formation of both Ce_2O_3 and CeO_2 in the presence of oxygen at high temperatures [7]. A variety of metastable intermediate states (CeO_{2-x}) of near-fluorite structure exist with oxygen vacancies randomly distributed [8]. The vacancy concentration and distribution depends on temperature and oxygen pressure, endowing CeO_2 with reducibility and wide applicability as an oxygen storage material within a multi-component oxidation catalyst [9].

Carbon monoxide (CO) is the product of incomplete combustion of carbon-based fuels. CO emissions must be avoided since the lethal gas binds strongly to hemoglobin, disabling it from delivering oxygen to bodily tissues. Further oxidation of CO to CO_2 is a highly exothermic reaction with a remarkably high ignition temperature at 609 °C.

The oxidation of CO is a useful probe reaction of the reducibility of CeO_2 -based catalysts, a key property impacting the activity of catalysts. CeO_2 is a good candidate for CO oxidation at non-UHV pressures due to active surface oxygen (both superoxo and peroxy) that react with the CO on the surface of ceria. During the oxidation process, CO initially reacts with active surface oxygen to form CO_3 [2–8] which then reacts with O_2 to yield CO_2 and regenerate active surface oxygen. These reactive oxygen intermediates arise from the Ce^{4+} – Ce^{3+} redox couple, and their formation is dependent on the ease of oxygen vacancy formation [10]. Atmospheric oxygen does not directly adsorb and dissociate at the vacant sites, but the redox process involving the formation and replenishing of oxygen vacancies on CeO_2 is described as a Mars van Krevelen (MvK) mechanism [11].

PROX over H_2 is an important reaction in proton-exchange membrane fuel cells (PEMFC), which exploit hydrogen as an energy source. The concentration of CO in the feed must be kept at an ultra-low level (<50 ppm) to prevent poisoning of the hydrogen oxidation electrode, typically made from noble metals [12,13]. Thus, elimination of the trace amount of CO from H_2 is required. One strategy to reduce the concentration of CO is via the water-gas shift reaction, where CO is oxidized by H_2O to CO_2 while producing H_2 , but this reaction often requires high(er) temperatures than an alternate approach.

The other approach is preferential oxidation using O_2 (PROX):

Selective adsorption of CO and suppression of hydrogen dissociation on the catalyst surface are essential to achieve PROX, which requires prudent selection of supported metals as binding sites because ceria itself is active towards both CO and hydrogen oxidation [14,15].

The surface properties of ceria can be modified by the deposition of noble metals. Common synthetic methods to deposit metals as nanoparticles on oxide supports include direct metal deposition on the surface of as-synthesized CeO_2 , or co-precipitation of the metal dopant with CeO_2 in a single step. The supported metal forms a strong interaction with the ceria

support at their interface, often decreasing the energy penalty for the formation of an oxygen vacancy. Therefore, tuning the interaction between metal and CeO_2 is vital to catalytic performance in oxidation reactions.

Ceria-based catalysts are well-studied and reviews on the surface chemistry [8], redox properties [3] and industrial application of bare ceria have been published [2,5]. Ceria-supported metal catalysts and other heterogeneous catalysts have been summarized in a number of reviews where the focus has been on the stability [16], surface chemistry [17,18] and catalysis of ceria-supported metal catalysts [6,19]. In addition, with the strong interest in single-atom catalysis, single atoms supported on ceria have been discussed and compared with other supports for small molecule catalytic chemistries [6,20–22]. Herein, the focus of this review is on topics related to oxidation of CO on CeO_2 -supported metal catalysts, with an emphasis on the difference in catalytic performance as an outcome of the different synthetic methods, structural/chemical properties of the ceria support, and choice of supported metal species. The catalyst's performance is mainly demonstrated by its reactivity and selectivity towards CO (rather than H_2) oxidation, while the reaction mechanism is either studied by DFT calculations or inferred from kinetic studies and/or experimental characterization of reaction intermediates.

2. CO oxidation on CeO_2 -supported nanoparticles

2.1. CO oxidation

Although bulk metallic gold is considered chemically inert, it shows great catalytic activity when deposited on an active CeO_2 support and dispersed as nanoparticles [23,24]. Low-temperature performance for CO oxidation has been widely reported on Au/CeO_2 . The activity of these catalysts, however, depends on the preparation method, the properties of the CeO_2 support, the size of the Au nanoparticles and the presence of moisture [24]. For example, Han et al. [25] prepared Au/CeO_2 following two synthetic routes – either via deposition of HAuCl_4 on a hydrothermally synthesized ceria support, or via co-precipitation of HAuCl_4 and $\text{Ce}(\text{NO}_3)_3$. The samples prepared via the first route showed a much higher activity and greater performance at lower temperature [25]. XPS analysis on the most active Au/CeO_2 demonstrated Au predominantly as Au^+ , which they proposed as the active species [25]. Guzman et al. [26] applied FTIR with CO as a probe molecule to quantify the concentration of Au^{3+} , Au^+ and Au^0 on Au/CeO_2 catalysts made by a deposition-precipitation method, and found the specific activity in CO oxidation ($\text{mol}_{\text{CO}} \text{g}_{\text{Au}}^{-1} \text{h}^{-1}$) almost linearly correlated with the concentration of Au^{3+} , while no correlation was found between the activity and the concentration of Au^+ and Au^0 . Carrettin et al. [27] found Au nanoparticles deposited on nanocrystalline CeO_2 demonstrated reactivity two orders of magnitude higher than Au/CeO_2 catalysts prepared by coprecipitation or deposition of Au on bulk CeO_2 .

Accounting for such differences in the details of the ceria support must consider size effects as it has been shown that although larger Au NPs can dissociate O_2 [28], their lower dis-

persions lead to lower specific activity. Very small Au clusters, by virtue of a decreased d-band occupancy, adsorb both CO and H₂ very strongly, and so become inactive for CO oxidation [29]. The zero-valent metal is not active for CO oxidation, even though it is almost always present, especially at PROX conditions [30]. Au⁺ at the CeO₂ interface, often formed under reaction conditions from Au³⁺, is a likely active site for selective CO oxidation at low temperatures, and these findings are in agreement with those on related catalysts such as Au/TiO₂ and Au/Fe₂O₃ [30].

The effect of humidity in the feed has been studied by Zhang et al. [31], who observed a reduced induction period and enhanced initial activity under humid conditions (Fig. 1 top). *In-situ* DRIFTS detected the presence of a surface COOH intermediate under both wet and dry conditions, which formed upon the interaction between adsorbed CO and surface hydroxyl groups [31]. The authors attributed the shorter induction time under humid conditions to the rapid formation of abundant COOH, since water readily dissociated in the vicinity of gold nanoparticles, whereas there was a limited amount of hydroxyl species available under dry conditions (Fig. 1, bottom) [31].

Fig. 1. (top) CO conversion versus time on stream over Au/CeO₂ catalysts under humid and dry conditions at 20 °C. (bottom) Schematic diagram of proposed mechanism for the induction period, where the hydroxyl groups migrate to and/or from the gold nanoparticles in (A) dry and (B) humid condition. Reprinted with permission from Ref. [31], copyright 2014, ACS Catalysis.

After the induction period, however, the reaction quickly transitioned into a fast deactivation phase under humid conditions due to the blockage of active sites by water molecules, while such deactivation was absent under dry conditions (Fig. 1, top) [31]. A subsequent deactivation stage, at a slower rate, was observed in both wet and dry conditions, due to the gradual accumulation of surface carbonate species, as identified by DRIFT measurements, which blocked the active Au sites [31].

Ceria-supported Pd nanoparticles also oxidize CO at ambient temperatures. Tereshchenko et al. [32] reported high catalytic activity on supported Pd/CeO₂ (111) at a loading of 5 wt% Pd and a dispersion of 50%–75% (1.5–2 nm), where the CO conversion reached 100% at 50 °C. Yang et al. [33] prepared Pd/CeO₂ via a laser vaporization at the same Pd weight loading (5 wt%) but with larger Pd nanoparticle sizes (5–10 nm), and reported 100% conversion at 108 °C. The difference in catalytic activity could be attributed to higher Pd dispersion in Tereshchenko's work, and higher activity on the CeO₂ (111) nanostructures [32].

The shape-dependent activity of Pd/CeO₂ nanocrystals has been compared by Hu et al. [34], who deposited 1.0 wt% Pd on different ceria nanocrystals and found Pd/CeO₂-rods (consisting of primarily (110) and (100) facets) were more reactive with a lower activation energy than Pd/CeO₂-cubes (only (100) facets) and Pd/CeO₂-octahedra ((111) and (100) facets). An XPS study conducted by the same group revealed the formation of Pd²⁺-O²⁻-Ce⁴⁺ linkages on both CeO₂-rods and CeO₂-cubes but with a higher stability on the rods exposing (110) facets (Fig. 2) [34]. This linkage readily provided nucleophilic oxygen and created oxygen vacancies. In contrast, PdO_x nanoparticles are the dominant form of Pd species on the CeO₂-octahedra exposing (111) surfaces (Fig. 2), which have a decreased tendency to form oxygen vacancies [34].

Pt/CeO₂ catalysts show low-temperature reactivity for CO oxidation from 20–80 °C [35–38]. A consensus is interfacial Pt-O-Ce moieties are the sites for the activation of CO

Fig. 2. XPS spectra of Pd 3d on Pd/CeO₂-rods, Pd/CeO₂-cubes and Pd/CeO₂-octahedra catalysts. The deconvoluted peaks at 336.8 eV (pink) and 337.7 eV (green) were assigned to Pd²⁺ and PdO_x species, respectively. Reprinted with permission from Ref. [34] copyright 2016, ACS Catalysis.

Fig. 3. XPS spectra of Pt 4f of (A) Pt/CeO₂-cubes, (B) Pt/CeO₂-rods and (C) Pt/CeO₂-octahedra catalysts. The deconvoluted peaks correspond to (blue) Pt⁰ and (red) Pt²⁺ species, respectively. Only Pt²⁺ species were observed on Pt/CeO₂-cubes and Pt/CeO₂-rods when the Pt weight loading was lower than 1%. Reprinted with permission from Ref. [38], copyright 2013, ChemCatChem.

[35,36,38–40]. However, the charge state of the interfacial Pt during CO oxidation is still debated. Morfin et al. [41] applied DRIFTS measurements and identified Pt^{δ+} and PtO species on Pt/CeO₂ catalysts synthesized from platinum tetraamine nitrate (Pt(NH₃)₄(NO₃)₂) and chloroplatinic acid (H₂PtCl₆) precursors, respectively. The latter catalysts showed poor reactivity towards CO adsorption and they claimed Pt^{δ+} (0 < δ < 2) species interacting with the CeO₂ support are more active than the deposited PtO species for CO oxidation. Similarly, Gao et al. [38] found the catalytic performance followed the order of Pt/CeO₂-rods > Pt/CeO₂-cubes > Pt/CeO₂-octahedra. However, as they increased the Pt weight loading on CeO₂-rods and CeO₂-cubes, the fraction of metallic Pt⁰ increased (Fig. 3) as well as the specific reaction rates (Table 1), which supported the conclusion that Pt⁰-CeO₂ ensembles are more active than Pt²⁺. Apparent disagreements in the literature may be related to the effect of metal particle size, since distributions can seldom be kept constant in comparative experiments.

Theoretical DFT studies have also investigated the oxidation of CO over metal nanoclusters supported on ceria surfaces. Au-based catalysts have received the most attention with DFT calculations. Song et al. [42] modeled three different CO oxidation mechanisms over a 32 atom-Au nanorod supported on CeO₂(110) (Au₃₂/CeO₂(110), Fig. 4). The first mechanism was a

Mars-van Krevelen (MvK) mechanism in which CO adsorbed at the Au nanorod-CeO₂ interface, followed by reaction with a ceria lattice oxygen. The generated oxygen vacancy is refilled by adsorption of gas phase O₂ and its facile dissociation (56 kJ/mol barrier) into a lattice O atom and a reactive O atom. The other two reaction paths start with O₂ adsorption at the Au₃₂/CeO₂(110) interface enabling the adsorbed O₂ to either directly react with adsorbed CO in a Langmuir-Hinshelwood mechanism (co-adsorption mechanism) or dissociate first into O atoms that then react with CO (step-wise mechanism).

All three candidate mechanisms were reported to be relevant to CO oxidation catalysis due to very similar overall reaction barriers, with the CeO₂(110) surface facilitating O₂ adsorption as well as dissociation in the stepwise mechanism. The proposed MvK mechanism is consistent with experimentally determined involvement of lattice O atoms in CO oxidation

[42], copyright 2013, Catalysis Science & Technology.

[43]. The dominant mechanism may, however, vary on the different terminated ceria surfaces. For metal clusters supported on $\text{CeO}_2(111)$, the MvK mechanism is not operative because of a less favorable oxygen vacancy formation energy than on the other CeO_2 facets. Kim et al. [44] concluded the MvK mechanism may only dominate at high temperatures on $\text{Au/CeO}_2(111)$ catalysts, and this appears true even at Au -defective $\text{CeO}_2(111)$ interface [42]. In the co-adsorption mechanism, the structure of the intact $\text{CeO}_2(111)$ surface would hinder O_2 adsorption at the interface, therefore, O_2 can only adsorb on the Au cluster [42]. The stepwise mechanism, requiring O_2 dissociation at the interface, may also be difficult at the $\text{CeO}_2(111)$ surface due to hindered O_2 adsorption at the interface [44]. MvK-facilitated CO oxidation with O_2 adsorption and activation occurring at O vacancies was also inferred over $\text{CeO}_2(100)$ surface from a combined DFT and experimental work over ceria cubes modeled as $\text{Au/CeO}_2(100)$ [45].

In related work, Song et al. [46] examined the oxidation of CO over Pd/CeO_2 catalysts over a 32 atom- Pd nanorod model supported on a reactive surface termination of ceria, $\text{CeO}_2(110)$. The entire MvK reaction mechanism for CO oxidation is similar to that over $\text{Au}_{32}/\text{CeO}_2(110)$ as described above, but the energetics of individual steps vary significantly. For $\text{Pd}_{32}/\text{CeO}_2$, the reaction of adsorbed CO with a lattice O atom proceeds with a barrier of 122 kJ/mol and an exothermicity of 20 kJ/mol, in sharp contrast to the negligible reaction barrier and high exothermicity during CO oxidation over $\text{Au}_{32}/\text{CeO}_2(110)$ reported by the same group. The difference arises from a much stronger Pd-CO bond. The barrier for O_2 dissociation occurring at the metal/ceria interface is similar for Au_{32} and Pd_{32} . Additionally, the latter half of the reaction cycle (CO reaction with dissociated O atoms) is different than on ceria-supported Au NPs. Dissociated O atoms migrate to the Pd NPs and adsorb more strongly than the O adsorbed at the Au/ceria interface. The barrier for the $\text{CO} + \text{O}$ reaction is very close to the reported barrier for CO oxidation on the $\text{Pd}(111)$ surface [47]. The study also concluded the co-adsorption and stepwise mechanisms, operable on $\text{Au}_{32}/\text{CeO}_2(110)$, could be ruled out on the $\text{Pd}_{32}/\text{CeO}_2$ due to a stronger CO adsorption on Pd_{32} , ultimately resulting in CO poisoning.

2.2. Preferential oxidation of CO in the presence of H_2

For CeO_2 -supported metal catalysts, the selectivity towards CO in the presence of excess H_2 requires selective CO adsorption and suppression of H_2 adsorption. Pd/CeO_2 catalysts are remarkably active for CO oxidation, but the reactivity decreases drastically in the presence of H_2 [48]. For example, under PROX conditions, the formation of Pd β -hydride was identified by Pozdnyakova et al. [49] using in situ XPS, and the hydride reacts rapidly with oxygen which suppressed CO oxidation. Increasing temperature led to higher CO_2 selectivity on Pd/CeO_2 catalysts due to decomposition of the hydride.

Pt/CeO_2 catalysts are good candidates for CO PROX reactions in excess hydrogen. The key for CO_2 selectivity was assumed to be the suppression of H_2 adsorption, due to water accumulation on the catalyst surface and blockage of the oxida-

tion sites for adsorbed H species [49,50]. As depicted by Pozdnyakova-Tellinger et al. [49,51], hydrogen spillover from Pt to the ceria support leads to formation of oxygen vacancies and surface water stabilized at the vacancies. The adsorbed water blocked subsequent adsorption of hydrogen at the vacant sites, while CO mainly adsorbed to metallic platinum. Gao et al. [38] compared the activity of Pt supported on different CeO_2 nanostructures for CO PROX and found the activity increases in the order octahedra < cubes < rods, which is consistent with the order of oxygen vacancy concentration as characterized by the intensity of the corresponding Raman bands. This result further emphasizes the role of oxygen vacancies in the oxidation of CO . In the above work, Pt/CeO_2 reaches CO_2 selectivity of 50%–80% below 50 °C when CO makes up ~1% of the feed stream. However, Polster et al. [39] found the selectivity decreases to 20% as the CO fraction drops to ~100 ppm, which indicates Pt/CeO_2 catalysts are inadequate for the PROX reaction with trace quantities of CO . The poor behavior at ultra-low CO concentration was explained by a change in reaction regime, as the reaction order of O_2 was 0.58 at low CO coverage (25 ppm) and ~0.02 at higher concentration (1%). This reaction order change indicates a change of rate limiting step, coverage regime, or a different reaction mechanism as the CO partial pressure varies. The authors proposed CO oxidation occurs on the Pt nanoparticles through a Langmuir-Hinshelwood (L-H) mechanism at low CO concentrations, whereas CO oxidation at higher concentrations occurred at the Pt-O-Ce interface through a Mars van Krevelen (MvK) mechanism [39]. In-situ DRIFTS demonstrate the adsorbed CO peak saturated at 650 ppm CO , and was unaffected by the presence of O_2 . This suggests the Pt surface becomes completely covered by CO at rather low CO pressures and reaction only occurs through MvK mechanism at the interface once the Pt surface is CO saturated. At low CO pressures where a L-H mechanism dominates, the rate of H_2 oxidation is significant as open Pt surface sites can also activate H_2 to react with bound O atoms [39].

The performance of Au/CeO_2 catalysts towards CO-PROX is highly dependent on the catalyst preparation method, and reported performance also varies among catalysts prepared by the same method. Luengnaruemitchai et al. [52] synthesized 1% Au/CeO_2 by co-precipitation, impregnation and sol-gel methods and the catalysts prepared by co-precipitation possessed both the highest CO conversion and selectivity as well as long-term stability. A temperature-programmed reduction (TPR) study by Arena et al. [53] indicated Au/CeO_2 synthesized by deposition-precipitation or combustion (urea ignition) showed higher activity than those synthesized by co-precipitation or incipient wetness. Scirè et al. [54] also found synthesis by deposition-precipitation resulted in more active and stable catalysts compared to co-precipitation. These conflicting results can be traced back to differences in Au dispersion, support surface area and removal of poisons, especially chloride, which arises from the common Au precursor, HAuCl_4 . High Au dispersions are clearly desirable, while co-precipitation can result in too much Au buried beneath the surface. Support surface area is important because higher sur-

face area suggests a greater number of adsorption sites for small NPs. Chloride removal down to a few ppm is critical because Au chlorides are resistant to reduction except at higher temperatures. Deposition-precipitation can sometimes result in easier chloride removal because the chlorides can be replaced by other ligands prior to surface deposition. Many of these competing effects can be delineated through XPS or even chemisorption techniques.

Deng et al. [55] synthesized low-content ($\text{Au} < 0.6 \text{ at\%}$) Au/CeO_2 via urea gelation/co-precipitation and deposition-precipitation followed by NaCN leaching for the removal of weakly bound gold. These catalysts possessed activity for CO-PROX, good redox cyclability, and stability over a wide range of temperatures. An XPS study showed all strongly-bound gold was cationic, and these cationic sites were involved in catalyzing the PROX reaction. Beyond conventional synthesis methods, Cargnello et al. [56] introduced carboxylic groups on the surface of monolayer-protected gold nanoparticles to direct ceria growth through covalent bonding between ceria and the carboxylic group (Fig. 5). They reported higher dispersion of Au nanoparticles and activity in the CO-PROX reaction, but lower accessibility of Au nanoparticle than the Au/CeO_2 catalyst synthesized by deposition-precipitation. The Au nanoparticles were at least partly encapsulated, with a portion completely buried in the nanostructured porous ceria [56].

The application of CuO/CeO_2 in CO PROX reactions was firstly reported by Avgouropoulos et al. [57], who prepared catalysts showing remarkable selectivity, activity, stability and tolerance to CO_2 . There is significant synergy between CuO and CeO_2 since CuO/CeO_2 shows much higher CO oxidation activity than either CuO or CeO_2 [13]. Comparison of CuO/CeO_2 catalysts with Au/CeO_2 demonstrate they can possess better CO_2 selectivity in spite of lower activity [54,57,58]. Similar to Au/CeO_2 , the activity of CuO/CeO_2 catalysts is highly dependent on the synthetic approach and parameters such as calcination temperature and loading, as summarized in a previous review [59]. For example, Chung et al. [60] prepared CuO/CeO_2 catalysts by co-precipitation at various pH values, and found higher pH led to a greater rate of CeO_2 nucleation, and increased concentration of interfacial Cu sites, reducibility of CuO and CO oxidation activity. Jung et al. [61] studied the influence of calcination temperature (500–900 °C) of CuO/CeO_2 prepared by co-precipitation. They found a volcano relationship between activity and calcination temperature with an optimum at 700 °C. Above 800 °C, phase separation between CuO and CeO_2 was

Fig. 5. Schematic representation of Au/CeO_2 catalysts prepared by directed growth of ceria around carboxyl-grafted Au nanoparticles, as described by Cargnello et al. Reprinted with permission from Ref. [56], copyright 2010, *Chemistry of Materials*.

detected by XRD and H_2 -TPR. This demixing decreased the quantity of active Cu-Ce-O species and decreased the activity for CO PROX. Maciel et al. [62] compared the activity of CuO/CeO_2 synthesized by a hydrothermal or precipitation approach with observation of higher activity and selectivity on the former catalysts. They attributed this to a smaller crystallite size of the hydrothermally-prepared catalysts, leading to better reducibility of the CuO nanoparticles, as characterized by SEM and H_2 -TPR.

Martinez-Arias and co-workers [63,64] studied various synthetic approaches to alter the interfacial area between CuO_x and CeO_2 , and thereby demonstrated, using multiple characterization techniques, that selective CO oxidation takes place at interfacial sites between CeO_2 and dispersed CuO_x . A correlation was established between PROX activity and the extent of reduction of the CuO_x entities. The H_2 oxidation was also shown to proceed immediately (thereby lowering CO oxidation) after onset of a major copper reduction to Cu^+ , indicating the active species for H_2 oxidation include partially reduced and dispersed copper oxide NPs, as well as fully reduced Cu(0) . XANES results (Fig. 6) illustrate how the onset of measurable interfacial Cu^+ corresponds to the onset of CO oxidation, while the bulk evolution of (first) Cu^+ and (second) Cu(0) correlates with the oxidation of H_2 .

Guo et al. [65] followed up on this work, preparing ceria nanoparticles with rod, cube, plate and polyhedral morphology by hydrothermal methods to support CuO_x . The CuO/CeO_2 -rod and CuO/CeO_2 -polyhedra catalysts displayed better low-temperature activity for CO PROX and a broader temperature range for high CO conversion. XPS revealed a higher con-

Fig. 6. Evolution of principal components detected by XANES during a CO-PROX over $\text{Cu}_{0.2}\text{Ce}_{0.8}\text{O}_2$ and evolved gases during the same run. Reprinted with permission from Ref. [63], copyright 2007, *Journal of the American Chemical Society*.

tent of Cu⁺ species in the more active catalysts, while Raman spectroscopy showed a higher concentration of oxygen vacancies, many of which would be located at interface sites. They also performed in situ DRIFTS measurements and inferred stronger metal-support interactions based on a weaker C-O bond in Cu⁺-CO species [65]. These results are consistent with those of Martinez-Arias and represent another example of the influence of CeO₂ morphology on catalytic activity [63,64].

Preferential CO oxidation over H₂ has also been studied with DFT methods over ceria supported copper catalysts. The DFT calculations using CuO/CeO₂ models demonstrate CuO_x clusters on CeO₂(111) were easily reduced to Cu⁺, improving the catalytic reactivity relative to CuO_x/CeO₂(001) which maintained Cu in a +2 oxidation state [66]. The facet-dependent reducibility during the PROX reaction has also been substantiated by DFT calculations on a Ce₆₀O₁₂₀ cluster model [67]. DFT results show enrichment of oxygen vacancies at the sites located at the intersection of (111) and (002) facets. A high concentration of Ce³⁺ species (Table 2) at the (111)/(002) intersection induces the formation of Cu⁺ (Cu²⁺ + Ce³⁺ → Cu¹⁺ + Ce⁴⁺). For CuO/CeO₂(spheres) and CuO/CeO₂(spindles), such intersections are exposed, with positive effects on PROX activity. These two catalysts possessed a wider temperature window for complete CO conversion than other Cu/CeO₂-based catalysts (rods, octahedra) comprised primarily of less reducible facets [68]. The higher temperature window for PROX was further explained by DFT calculations demonstrating CuO_x nanoparticles interacted more strongly with the CeO₂ surface, thereby making them highly resistant towards reduction to Cu(0). Cu(0) is responsible for H₂ activation and thus its presence contributes to CO₂ selectivity loss. The catalytic synergy for PROX on Cu/CeO₂ therefore arises from a combination of high surface area, a stable (Cu⁺ or Cu^{(2-δ)+} in the oxidized form) oxidation state of copper, high concentration of oxygen vacancies, as well as a strong interaction between CuO_x and CeO_{2-x} [67].

Jing et al. [69] reported improved catalytic performance for PROX, including an expanded temperature window, with Au/CeO₂-CuO compared to CuO/CeO₂ catalysts. On the basis of DFT calculations, Au clusters were expected to be mainly located on the CeO₂(111) surfaces. The better performance was attributed to these Au species both stabilizing CuO_x against reduction and promoting the reduction of ceria to supply active lattice oxygen. Prevention of the reduction of copper species hindered H₂ oxidation. DFT results demonstrated an increase in Au content led to an increase in the number of active interfacial sites and thus decreases the activation barrier for CO oxidation, consistent with experimental observations.

Table 2

Calculated GGA and GGA+U (U = 5 eV) energies for oxygen vacancy formation energy (E_{vac}) on different CeO₂ surfaces. Reproduced with permission from Ref. [67], Copyright 2018, Applied Catalysis B: Environmental. Elsevier.

CeO ₂ facet	GGA (eV)	GGA+U (eV)
(111)	1.69	3.23
(002)	0.67	2.81
(111)/(002)	0.59	2.39

3. CO oxidation on CeO₂-supported single atom catalysts

CO oxidation represents a good probe reaction of ceria-supported single-atom catalysts since work on supported nanoparticle catalysts demonstrate the influence of support properties and the identity of the metal on the observed performance. Single atoms are less effective for the dissociative adsorption of H₂, which contributes to the selectivity towards CO₂ during PROX [70]. Due to a limited number of reported work on the application of CeO₂-supported single atom catalysts in the CO PROX reaction, CO PROX will be discussed along with CO oxidation.

Pt₁/CeO₂ has been extensively studied, but it is unclear whether single atoms are more (or less) active than Pt clusters. We also compare to studies considering Pt₁/TiO₂ catalysts, since TiO₂ can similarly serve as a redox-active support. Ding et al. [71] claimed Pt single atoms on active supports showed little low-temperature activity due to their strong binding of CO. They intentionally synthesized Pt/TiO₂ with different Pt weight loadings to guarantee the coexistence of Pt nanoparticles and single atoms, and performed in situ FTIR to compare the binding strength of CO on both Pt species. After saturation of both Pt sites with CO, and a He purge, the band related to Pt nanoparticles decreased quickly while the band associated with CO bound to single Pt atoms remained (Fig. 7) [71]. However, DeRita et al. [72] suggested the Pt species binding CO strongly may actually be small oxidized Pt clusters formed at elevated temperatures under oxidative conditions, whereas Pt single atoms pre-reduced in H₂ bind CO weakly [73]. In situ FTIR spectra revealed CO adsorbed on Pt single atoms quickly diminished upon Helium purge at room temperature (Fig. 8(A)), whereas CO adsorbed on Pt nanoparticles and oxidized Pt clusters desorbed under temperature-programmed oxidation conditions (Fig. 8(B) and 8(C)). The reduced Pt₁/TiO₂ catalysts showed 2-fold greater turnover frequency than 1 nm Pt clusters, but poorer stability [73]. The effect of hydrogen reduction was also studied by Li et al. [74] on Pt₁/CeO₂ catalysts, who applied in-situ DRIFTS, XAS and XPS techniques on Pt₁/CeO₂ catalysts pre-reduced in 5% H₂/Ar at 350 °C. They identified

Fig. 7. IR spectra of CO adsorbed Pt single atoms and nanoparticles on wet-impregnated Pt/TiO₂ and Pt/ZrO₂ upon O₂ exposure at 100 °C. Reprinted with permission from Ref. [71], copyright 2015, *Science*.

Fig. 8. DRIFTS spectra of (A) CO adsorbed at room temperature and saturation coverage on a pre-reduced 0.05 wt% Pt₁/TiO₂ single-atom catalysts, (B) CO adsorbed to a reduced 1 wt% Pt/TiO₂ catalyst during He purge and TPO ramp, (C) CO adsorbed to an oxidized 1 wt% Pt/TiO₂ catalyst during He purge and TPO ramp. the dynamic formation of bimetallic Pt-Ce sites as a new type of active species during hydrogen reduction, which was critical for the subsequent oxidation reaction.

Water was reported to improve the reactivity of the atomically dispersed ionic Pt²⁺ in CO oxidation. The promoting effect of water was first studied by Wang et al. [75] by pulsing CO and ¹⁶O₂ with isotopically-labeled H₂¹⁸O. They detected nearly half the amount of CO₂ product in the form of C¹⁶O¹⁸O and the formation of H₂¹⁶O at 98 °C, which indicated water was directly involved in the reaction. The DFT results suggested formation of a carboxyl intermediate as water dissociated into H and hydroxyl groups, the latter of which interacted with adsorbed CO on Pt single sites (Fig. 9) [75]. Nie et al. [76] treated Pt₁/CeO₂ with steam at 750 °C to improve the CO oxidation activity, which was sustained even in the absence of further water for over 300 h. H₂-TPR results showed steam treatment created a

new type of activated oxygen species, which according to DFT calculations was a surface hydroxyl (O_{lattice}[H]) [76]. From DFT calculations, an oxygen vacancy migrated to the vicinity of a Pt single atom, a water molecule filled the vacancy with an oxygen atom, and the hydrogen atoms reacted with lattice oxygen atoms in CeO₂ to form O_{lattice}[H] (Fig. 9). The catalyst was stable up to 800 °C in an oxidizing environment [76].

Au₁/CeO₂ also showed good reactivity and stability for CO oxidation, as well as CO₂ selectivity in CO PROX. Wang et al. [77] reported 0.12 wt% Au₁/CeO₂ showed 90% CO conversion at 90 °C, and stability over 1000 min. time-on-stream, which they attributed to strong metal-support interactions between Au₁ and CeO₂. Qiao et al. [70] reported Au₁/CeO₂ was highly active, CO₂-selective with greater stability than supported Au nanoparticles; single atoms supported on CeO₂ displayed >99.5% CO conversion over a wide temperature range with

Fig. 9. Left: DFT simulated reaction mechanism for CO oxidation on steam-treated Pt₁/CeO₂ (111) surface. Right: illustration of steam-treatment effects on the atomically dispersed Pt₁/CeO₂ catalysts. Reprinted with permission from Ref. [76], copyright 2017, *Science*.

almost zero H_2 conversion. DFT calculations for H_2 oxidation on Au_1/CeO_2 suggested an Eley-Rideal mechanism with a much higher activation barrier than CO oxidation, indicating single atoms of Au cannot effectively dissociate H_2 [70].

CO oxidation on single Pd atoms supported on rod- and cube-shaped ceria nanostructures was investigated by Spezzati et al. [78,79]. A 1 wt% $\text{Pd}_1/\text{CeO}_2(111)$ catalyst showed reactivity at temperatures as low as 50 °C, and DFT calculations revealed the reaction proceeded through a catalytic redox cycle with PdO and PdO_2 as the active species [78]. $\text{Pd}_1/\text{CeO}_2(100)$ was less active than $\text{Pd}_1/\text{CeO}_2(111)$ due to a lower fraction of active Pd species, i.e. single Pd atoms in the oxidized form [79]. DFT calculations of CO oxidation on $\text{Pd}_1/\text{CeO}_2(100)$ indicate the catalytic cycle requires the participation of lattice oxygen from CeO_2 [79]. $\text{Pd}_1/\text{CeO}_2(111)$, however, is reported to follow a Langmuir Hinshelwood mechanism (co-adsorbing CO and O_2) to generate active species PdO and PdO_2 . Consequently, the activation barrier for CO oxidation for Pd/ $\text{CeO}_2(111)$ was much lower (29 kJ/mol) compared to the barrier on $\text{CeO}_2(100)$ (highest barrier 63 kJ/mol), consistent with the higher CO oxidation activity at Pd/ $\text{CeO}_2(111)$ observed experimentally.

Based on the above results, PdO_x species on $\text{CeO}_2(111)$ should be more active for CO oxidation than Pd adatom species on ceria which was supported by DFT studies and microkinetic simulations at 27 °C [80]. However, Pd doped into CeO_2 (square planar) should be less active due to weaker adsorption of CO, no matter the surface facet. For Pd-doped $\text{CeO}_2(110)$, Song et al. [46] reported CO adsorption occurs on the stoichiometrically-doped surface only. After the lattice oxygen is removed to form CO_2 via a MvK mechanism, the doped Pd relocates to a subsurface position such that O atoms repel CO and inhibit its adsorption. They also reported DFT studies for CO oxidation over Pd single atoms on $\text{CeO}_2(110)$ surfaces (Fig. 10) in parallel with the studies over Pd nanorod clusters supported on the same ceria facet (cited in the CO oxidation over NP section). The Pd^{2+} single atom sits in a 4-fold hollow site resulting in two

Ce^{3+} atoms, and adsorbs CO weakly. However, once CO is adsorbed, Pd adatoms adjacent to O atoms of the ceria surface, facilitate the formation of CO_2 more so than Pd NPs. Since the dissociative adsorption of O_2 is much stronger on Pd NPs than Pd adatoms (−158 vs −77 kJ/mol), strong O binding also makes the oxidation step more difficult on Pd NPs. Therefore, despite the weaker CO and O adsorption, atomically dispersed Pd on $\text{CeO}_2(110)$ are more active than NPs.

The mechanism of CO oxidation on Au adatoms over ceria surfaces has been studied by DFT. Song et al. [81] postulated a mechanistically similar (to adatom Pd/ CeO_2) MvK catalytic cycle on Au adatoms on $\text{CeO}_2(110)$. Details of the surface termination of the ceria support were considered crucial. CO oxidation over single Au adatoms on $\text{CeO}_2(111)$ appeared to be impossible due to difficulty in O_2 dissociation in the second half of the MvK cycle (healing the O-vacancy and CO removal as CO_2 with the dissociated O adatom). However, on Au/ $\text{CeO}_2(110)$, the more open surface allowed for the coordination of O_2 between the Au adatom and the vacancy site. Furthermore, Au adatoms are reported to be negatively charged on oxygen deficient $\text{CeO}_{2-x}(111)$ [82]. Considering the typical dominance of the (111) surface in larger particles, this may explain the observation that sintering of Au atoms into clusters sometimes leads to an increase in the catalytic activity, as other reaction pathways become accessible as described in Section 2. Reactivity of Au adatoms for CO oxidation has been reported over step sites on a $\text{CeO}_2(111)$ slab (by adding a Ce_6O_{12} wire) [83], but again CO oxidation by lattice oxygen is found to be the rate-determining step (0.83 eV). Recently, Wang et al. postulated, on the basis of ab initio MD simulations at temperatures of 300 and 700 K, a new catalytic mechanism involving single atoms for CO oxidation on Au/ $\text{CeO}_2(111)$ catalysts, arising from a transient $\text{Au}^+\text{-CO}$ reaction species [83,84]. During the oxidation of CO, the Au^+ acts as a charge acceptor for CO. This $\text{Au}^+\text{-CO}$ species considerably lowers the barrier for CeO_2 reduction, thereby facilitating oxygen adsorption.

4. Conclusions

Supporting metal species on CeO_2 tremendously boosts the reactivity and increases the low-temperature performance towards CO oxidation. Metal deposition on a ceria surface creates an active interface and the metal-support synergy can provide a viable reaction route following a Mars van Krevelen mechanism, where the supported metals serve as adsorption sites for CO, which is oxidized by interfacial oxygen. Metal-support interactions may lead to positively charged metal species, which show much higher reactivity and selectivity compared to CO oxidation on metallic nanoparticles, even though they may both follow Langmuir-Hinshelwood mechanism. Reactivity towards the oxidation of CO is dependent on the dispersion of metal species, the chemical properties of the ceria support, and the extent of metal-support interaction, all of which can be tuned by the structural and chemical properties of the ceria support. Details of the catalyst synthetic methods control such properties, for example choice of metal precursors, how they initially interact with the supports, and pre-

Fig. 10. Reaction mechanism of CO oxidation on the $\text{Pd}_1/\text{CeO}_2(110)$ model. (color scheme: gray = C, red = O; white = Ce^{4+} ; cyan = Ce^{3+} ; blue = Pd). The electron density difference plot for CO adsorption on $\text{Pd}_1/\text{CeO}_2(110)$ is inserted next to the structure (state ii). The blue and yellow colors indicate respectively a decrease and an increase in the electron density. Reprinted with permission from Ref. [46], copyright 2015, *Journal of Physical Chemistry C*.

treatment conditions before reaction. Compared to supported nanoparticles, small(er) nanoclusters and single atoms have higher dispersion, are generally less active than their nanoparticle counterpart for the low-temperature oxidation reactions surveyed here [32,78]. A possible explanation is that on nanoparticles, a bimolecular Langmuir-Hinshelwood mechanism on the surface of nanoparticles may be paired with a Mars van Krevelen mechanism at the metal-support interface, whereas the latter mechanism dominates on single atoms as the binding sites are isolated from one another. A direct comparison between ceria-supported nanoparticles versus single atoms would shed light upon the difference and/or similarity in the mechanism of CO oxidation. The challenge of such comparative study is ensuring single atom catalysts contain only single atoms, while nanoparticle-based catalysts are void of single atoms. Confirmation of either outcome is challenging, in general, due to the lack of statistically relevant data that quantifies this type of data beyond a limited set of electron micrographs.

The competitive adsorption between CO and H₂ is crucial in determining the selectivity in CO PROX reactions. According to relevant publications, Pt, Au and Cu nanoparticles are promising candidates due to their stronger interaction with CO than H₂. However, most of the studies evaluated the CO₂ selectivity under relatively high CO concentrations (~1%) where saturated adsorption of CO on all metal sites is expected, whereas high CO₂ selectivity at much lower CO concentrations (< 50 ppm) is required to meet practical requirements. Single-atom catalysts show great potential for PROX of CO in the presence of H₂ due to their inability to dissociatively adsorb H₂, and more studies understanding the mechanism of PROX on single-atom catalysts are anticipated. Single-atom catalysts show great potential

for PROX of CO in the presence of H₂ due to the nature of single sites and their inability to dissociatively adsorb H₂, yet few studies have been reported on CO-PROX on such catalysts. More studies on the activity and CO₂-selectivity of PROX on ceria-supported single-atom catalysts, the comparison to supported nanoparticles, and understanding of the mechanisms, are anticipated.

摘要: 氧化铈独特的氧化还原性能使其适合用作氧化反应中的催化剂或载体。氧化铈负载的过渡金属纳米粒子或孤立的单原子提供了金属-载体界面, 从而降低了去除界面氧原子的能耗, 提供了可以参与Man Van Kulvian氧化过程的活性氧物种。CO氧化是测试氧化铈负载催化剂还原性的主要探针反应, 并且它常见于在相对低温下消除CO的各种应用中。在过量H₂中优先氧化CO(PROX)反应可控制CO浓度达到超低水平, 以防止氢氧化电催化剂中毒。催化剂在CO氧化反应中的活性和在PROX反应中对CO和H₂的选择性取决于金属物种的种类和分散性、CeO₂的结构和化学性质以及催化剂的合成方法。在这篇综述中, 我们总结了最近发表的关于CeO₂负载的金属纳米粒子和单原子催化CO氧化和PROX反应的相关工作; 以及不同的负载金属和同种金属在普通CeO₂表面上的反应性。我们还总结了密度泛函理论计算中提出的最可能的反应机理; 并且讨论了各种负载型金属在PROX反应中影响CO氧化选择性的因素。

关键词: 氧化铈; CO氧化; 金属纳米粒子; 单原子; PROX
